

Velkscale Modeling Report - 26 September 2026

CONFOEDERATIO,
RESEARCH DIVISION (CRD).

Aust Kätzchen, CRD

Section 1. Revised System

Previous log: [Velkscale Modeling Report - 25 September 2026](#)

Due to time constraints, I do not attempt to make notations consistent between modelling reports, only a similar input/output contract with variable names.

Raw code was chunked into GPT-6 Astra with the assumption that it could reproduce a valid system via Curry-Howard correspondence, but take this as a whiteboard explanation rather than a rigid formalisation. In my experience it produces inconsistent definitional notation between turns, with strange stylistic choices. Where necessary I have put down manual notes or reformatted things I caught.

Is the system closed? Due to floating point and ordering problems, it is heuristically (approximately) closed, but just not actually closed ('tis the life of statistics!) So why bother with this exercise? Because I will need it in my future notes when I document the exact methodologies used in Velkscale 1.0. Anyways.

Below is the mathematical system implemented by the **default Whittaker–Henderson path** (PAVA is also an option, see preceding Modeling Report), followed by the births/deaths and migration pipelines.

Abstract.

Outline:

1. Ensemble multinomial logit (age/sex)
2. Whittaker-Henderson (Huber loss) at global/ISO3 level constraints (age/sex)
 1. How it started: historical demography
 2. How it's going: signal processing
3. WLS with Tukey's fences (migration)
4. Rogers-Castro age/sex scheduling for migration
 1. I took the code for this distribution from the most egregious R code to ever grace the eyes of man:

https://raw.githubusercontent.com/AppliedDemogToolbox/Hunsinger_MMSRCode/master/MMSRCode.R (thanks, Berkeley). True human, artisan slop.

2. Original Rogers-Castro paper for those that don't want their eyes to bleed:

<https://pure.iiasa.ac.at/id/eprint/1543/1/RR-81-030.pdf>

5. Global migration adjusted to sum to 0 (after all, every emigrant must immigrate somewhere, migration is a globally closed system)

6. Computed OLS births/deaths and scaling via cohort attribution, residuals post-migration

Also professions are being reprocessed using an additive log ratio (ALR) compositional model but I am still crossing my fingers above the campfire for how that will turn out. Ask Economics (vistacitus@confoederatio.org) what's going awry, please.

1. Notation and execution order

Suppress the cell/year subscripts where they would obscure the equations.

Let the age bands be indexed by $(a = 0, \dots, 17)$, with lower-age labels

$$(0, 1, 5, 10, \dots, 80).$$

The implemented band widths and midpoints are

$$w_a = \begin{cases} 1, & a = 0, \\ 4, & a = 1, \\ 5, & a \geq 2, \end{cases} \quad x_a = \sum_{b < a} w_b + \frac{w_a}{2}.$$

Thus the terminal band is computationally treated as width five, even if its source interpretation is 80+.

Let (t^-) be the preceding HYDE time point and define

$$h_t = t - t^-, \quad g_{i,t} = \frac{\Delta P_{i,t}}{h_t}.$$

The code substitutes $(h_t = 1)$ where there is no preceding time point.

For model covariates, define

$$\tilde{t} = \min(t, 2023), \quad \tilde{X}_{i,t} = X_{i,\tilde{t}}.$$

The population used specifically for age–sex clamping is also year-capped:

$$P_{i,t}^A = P_{i,\tilde{t}}.$$

The subsequent birth/death and migration stages generally load $(P_{i,t})$, **not** $(P_{i,t}^A)$.

To obtain the fully reconciled result, the effective execution order is:

1. reconstruct/composite age–sex populations;
2. construct and fit birth/death models;
3. construct and fit migration models;
4. generate migration outputs;
5. execute the final birth/death clamping and reconciliation.

The three classes do not themselves enforce this cross-class order.

2. Age–sex reconstruction

2.1 Assemble training targets

Let $(T_{i,t,a}^s)$ denote the selected age–sex target:

$$T_{i,t,a}^s = \begin{cases} H_{i,t,a}^s, & t < 1950, \\ U_{i,t,a}^s, & 1950 \leq t < 2015, \\ W_{i,t,a}^s, & t \geq 2015 \text{ and WorldPop available,} \\ U_{i,t,a}^s, & t \geq 2015 \text{ otherwise, if available.} \end{cases}$$

Here (H, U, W) denote the HMD-, UNWPP-, and WorldPop-derived rasters.

Under normalized soft-target MNL training, define

$$q_{i,t,a}^s = \frac{T_{i,t,a}^s}{\sum_{r,b} T_{i,t,b}^r}.$$

The default target-year domain is available HYDE years from 1750 through 2025.

2.2 Fit a separate intercept-free MNL for each target year

For training anchor (τ) ,

$$p_a^{s,(\tau)}(X) = \frac{\exp(X^\top \beta_{\tau,a}^s)}{\sum_{r,b} \exp(X^\top \beta_{\tau,b}^r)}.$$

With the assumed normalized-target likelihood,

$$\hat{\beta}_\tau \approx \underset{\beta}{\operatorname{argmin}} \left[- \sum_{i \in \mathcal{I}_\tau} \sum_{s,a} q_{i,\tau,a}^s \log p_a^{s,(\tau)}(\tilde{X}_{i,\tau}) \right].$$

Default wrapper settings are:

$$\lambda_{\text{MNL}} = 0, \quad \text{learning rate} = 0.1, \quad \text{maximum iterations} = 50, \quad \text{tolerance} = 10^{-4},$$

with sample limit 15,000.

Unspecified by the supplied code: whether the helper uses normalized cell compositions, count-weighted likelihood, or another observation-weighting convention. That changes the fitted coefficients, but not the downstream equations.

2.3 Construct coverage and temporal weights

Let (n_τ) be the saved training sample count. Its fallback is 1,000.

Define

$$c_\tau = \left(\frac{n_\tau}{n_{\max}} \right)^{0.3}, \quad \omega_\tau = \frac{c_\tau}{\sum_\nu c_\nu}.$$

For prediction year $(t \geq 1500)$,

$$v_\tau(t) = \frac{\omega_\tau e^{-|t-\tau|/50}}{\sum_\nu \omega_\nu e^{-|t-\nu|/50}}.$$

If a same-year model exists,

$$\alpha_\tau(t) = 0.8v_\tau(t) + 0.2 \mathbf{1}_{\{\tau=t\}}.$$

Otherwise,

$$\alpha_\tau(t) = v_\tau(t).$$

The assumed probability-mixture prediction is

$$p_{i,t,a}^s = \sum_\tau \alpha_\tau(t) p_a^{s,(\tau)}(\tilde{X}_{i,t}).$$

Before 1500, an externally supplied premodern model replaces this ensemble:

$$p_{i,t,a}^s = p_a^{s,\text{pre}}(\tilde{X}_{i,t}), \quad t < 1500.$$

Its construction is absent from the supplied files. If it is missing, the code does not provide a dependable pre-1500 ensemble fallback.

2.4 Aggregate preliminary populations into country bins

Let $(b(i))$ be the modern ISO3 bin of cell (i) , with one additional bin for unmapped cells.

Let $(\mathcal{E}_{b,t})$ contain eligible cells in bin (b) :

- $(P_{i,t}^A \geq 0.01)$;

- not selected for the pre-1950 HMD bypass.

The preliminary country cohort counts are

$$R_{b,t,a}^s = \sum_{i \in \mathcal{E}_{b,t}} P_{i,t}^A p_{i,t,a}^s.$$

Define combined counts and density:

$$R_{b,t,a} = R_{b,t,a}^f + R_{b,t,a}^m, \quad d_{b,t,a} = \frac{R_{b,t,a}}{w_a}.$$

Only the suffix ($a \geq 2$), beginning with ages 5–9, is graduated.

Its mean density is

$$\bar{d}_{b,t} = \frac{\sum_{a=2}^{17} R_{b,t,a}}{\sum_{a=2}^{17} w_a},$$

and normalized observations are

$$y_{b,t,a} = \frac{d_{b,t,a}}{\bar{d}_{b,t}}, \quad a \geq 2.$$

2.5 Apply default robust Whittaker–Henderson graduation

Define the Huber loss

$$\rho_\delta(e) = \begin{cases} \frac{1}{2}e^2, & |e| \leq \delta, \\ \delta|e| - \frac{1}{2}\delta^2, & |e| > \delta. \end{cases}$$

For each nonempty country suffix, the intended optimization is

$$\hat{z} \approx \underset{z_a \geq 0, a=2, \dots, 17}{\operatorname{argmin}} \left[\sum_{a=2}^{17} w_a \rho_{0.05}(z_a - y_a) + \frac{20}{2} \sum_{a=2}^{15} (z_{a+2} - 2z_{a+1} + z_a)^2 \right].$$

Default monotonicity penalty is zero:

$$\mu_{\text{WH}} = 0.$$

Thus **the default Whittaker path does not require decreasing age density**.

The implementation performs at most 200 alternating coordinate sweeps, using KKT residual tolerance (10^{-5}). It returns the current iterate even if it has not reached that tolerance.

Restore the suffix population through

$$k_{b,t} = \frac{\sum_{a=2}^{17} R_{b,t,a}}{\sum_{a=2}^{17} w_a \bar{d}_{b,t} \hat{z}_{b,t,a}}.$$

The graduated combined counts are

$$G_{b,t,a} = \begin{cases} R_{b,t,a}, & a < 2, \\ k_{b,t} w_a \bar{d}_{b,t} \hat{z}_{b,t,a}, & a \geq 2. \end{cases}$$

Raw country-level within-age sex shares are preserved:

$$G_{b,t,a}^s = G_{b,t,a} \frac{R_{b,t,a}^s}{R_{b,t,a}}.$$

This expression assumes ($R_{b,t,a} > 0$). Empty ages use a supplied/default sex-ratio prior if available, otherwise equal shares.

2.6 Scale cells and restore each cell's population

Define

$$k_{b,t,a}^s = \begin{cases} G_{b,t,a}^s / R_{b,t,a}^s, & R_{b,t,a}^s > 0, \\ 1, & R_{b,t,a}^s = 0. \end{cases}$$

For a modeled cell,

$$N_{i,t,a}^{s,\text{model}} = P_{i,t}^A \frac{p_{i,t,a}^s k_{b(i),t,a}^s}{\sum_{r,c} p_{i,t,c}^r k_{b(i),t,c}^r}.$$

If the denominator vanishes, each of the 36 categories receives ($P_{i,t}^A/36$).

For an HMD-bypass cell before 1950,

$$N_{i,t,a}^{s,\text{clamp}} = P_{i,t}^A \frac{H_{i,t,a}^s}{\sum_{r,c} H_{i,t,c}^r}.$$

Otherwise,

$$N_{i,t,a}^{s,\text{clamp}} = N_{i,t,a}^{s,\text{model}}.$$

Eligible clamped cells therefore satisfy

$$\sum_{s,a} N_{i,t,a}^{s,\text{clamp}} = P_{i,t}^A.$$

Country cohort totals need not remain equal to ($G_{b,t,a}^s$), because the final normalization is cell-specific.

2.7 Composite final age–sex populations

Selection occurs by available cohort/year raster:

$$N_{i,t,a}^s = \begin{cases} U_{i,t,a}^s, & 1950 \leq t < 2015, U \text{ available,} \\ W_{i,t,a}^s, & 2015 \leq t \leq 2025, W \text{ available,} \\ U_{i,t,a}^s, & 2015 \leq t \leq 2025, W \text{ absent, } U \text{ available,} \\ N_{i,t,a}^{s,\text{clamp}}, & \text{otherwise.} \end{cases}$$

The selected source rasters are copied directly; this final stage does not renormalize them.

3. Demographic denominators for births and deaths

3.1 Birth denominator

The infant-population proxy is

$$Q_{i,t}^B = N_{i,t,0}^f + N_{i,t,0}^m.$$

3.2 Death denominator

Estimate recent local growth:

$$r_{i,t} = \begin{cases} \frac{\log(P_{i,t}/P_{i,t-})}{h_t}, & P_{i,t-} > 0, \\ 0, & \text{otherwise.} \end{cases}$$

If the preceding population raster is absent, the code substitutes current population, also producing ($r = 0$).

For each sex, define growth-adjusted age density:

$$S_{i,t,a}^s = \frac{N_{i,t,a}^s}{w_a} e^{r_{i,t} x_a}.$$

Fit the weighted non-increasing isotonic projection:

$$\hat{S}_{i,t}^s = \underset{z_0 \geq z_1 \geq \dots \geq z_{17}}{\operatorname{argmin}} \sum_{a=0}^{17} w_a (z_a - S_{i,t,a}^s)^2.$$

Define the adjacent-age hazard proxy

$$\hat{\mu}_{i,t,a}^s = \begin{cases} \frac{\hat{S}_{i,t,a}^s - \hat{S}_{i,t,a+1}^s}{\hat{S}_{i,t,a}^s (x_{a+1} - x_a)}, & \hat{S}_{i,t,a}^s > 0, a < 17, \\ 0, & \hat{S}_{i,t,a}^s = 0, a < 17. \end{cases}$$

The terminal hazard is

$$\hat{\mu}_{i,t,17}^s = \begin{cases} 1/5, & \hat{S}_{i,t,17}^s > 0, \\ 0, & \text{otherwise.} \end{cases}$$

The death denominator is

$$Q_{i,t}^{D_s} = \sum_{a=0}^{17} N_{i,t,a}^s \hat{\mu}_{i,t,a}^s.$$

This is an age-structure-derived proxy, not mortality identified independently from migration and fertility history.

4. Common linear-model and calibration machinery

The three vital-event models and the migration model share essentially the same prediction/calibration structure.

Let

$$v \in \{B, D_f, D_m, M\}.$$

4.1 Training targets

Let $(A_{i,t}^v)$ denote selected source vital-event counts: HMD before 1950, UNWPP thereafter.

For births,

$$Y_{i,t}^B = \min \left(1.5, \frac{A_{i,t}^B}{Q_{i,t}^B} \right).$$

For deaths,

$$Y_{i,t}^{D_s} = \min \left(3, \frac{A_{i,t}^{D_s}}{Q_{i,t}^{D_s}} \right).$$

These targets require:

$$A_{i,t}^v > 0, \quad Q_{i,t}^v \geq 1,$$

and, when the population raster exists,

$$P_{i,t} \geq 10000.$$

For migration, using UNWPP vital counts,

$$A_{i,t}^M = g_{i,t} - \left(A_{i,t}^{B,U} - A_{i,t}^{D_f,U} - A_{i,t}^{D_m,U} \right),$$

and

$$Y_{i,t}^M = \text{clip} \left(\frac{A_{i,t}^M}{P_{i,t}}, -1, 1 \right), \quad P_{i,t} \geq 1.$$

Migration training targets are generated only for selected years ($t \geq 1950$).

In this residual construction, missing numeric source values are replaced with zero; negative birth/death values are also set to zero.

4.2 Year-specific ridge fits

Using (Z) for the linear-model design vector,

$$\hat{\theta}_\tau^v = \underset{\theta}{\operatorname{argmin}} \left[\sum_{i \in \mathcal{I}_\tau^v} \left(Y_{i,\tau}^v - Z_{i,\tau}^\top \theta \right)^2 + \theta^\top J \theta \right].$$

The wrapper's default ridge parameter is one.

Here $(J = I)$ for fully penalized coefficients, or has a zero intercept entry if the helper fits an unpenalized intercept. **The supplied wrappers do not establish the linear helper's intercept or loss-normalization convention.**

4.3 Signed geometric-mean fallback

For each coefficient (j) , let (K) be the number of contributing yearly models and define

$$\mathcal{P}_j = \{\tau : \hat{\theta}_{\tau,j}^v > 0\}, \quad \mathcal{N}_j = \{\tau : \hat{\theta}_{\tau,j}^v < 0\}.$$

Under your supplied aggregation assumption,

$$\bar{\theta}_j^v = \frac{|\mathcal{P}_j|}{K} \exp \left(\frac{1}{|\mathcal{P}_j|} \sum_{\tau \in \mathcal{P}_j} \log \hat{\theta}_{\tau,j}^v \right) - \frac{|\mathcal{N}_j|}{K} \exp \left(\frac{1}{|\mathcal{N}_j|} \sum_{\tau \in \mathcal{N}_j} \log |\hat{\theta}_{\tau,j}^v| \right).$$

An empty sign group contributes zero.

Then

$$\theta^v(t) = \begin{cases} \hat{\theta}_t^v, & \text{same-year model exists,} \\ \bar{\theta}^v, & \text{otherwise,} \end{cases}$$

and raw predictions are

$$z_{i,t}^v = Z_{i,t}^\top \theta^v(t).$$

4.4 Construct target-factor bounds

For a sorted target sample of length (n), the implemented empirical quantile is

$$Q_p = y_{(\lfloor np \rfloor)}$$

using zero-based indexing.

For each year with sampled targets,

$$\ell_t^v = Q_{0.01}(Y_t^v), \quad u_t^v = Q_{0.99}(Y_t^v).$$

Over the selected processing years,

$$\ell_*^v = \min_t \ell_t^v, \quad u_*^v = \max_t u_t^v.$$

The sampling rules differ:

- Births/deaths: every seventh pixel, retaining positive targets; effective count ($n^v_{t=7 \times}$) retained sample size.
- Migration: every seventeenth pixel, retaining ($P > 10000$) and ($|Y^M| > 10^{-10}$); (n_t^M) is retained sample size.

For an observed-target year, let

$$\varepsilon_t^v = e^{-n_t^v/15}.$$

The final bounds are

$$L_t^v = (1 - \varepsilon_t^v)\ell_t^v + \varepsilon_t^v\ell_*^v,$$

$$U_t^v = (1 - \varepsilon_t^v)u_t^v + \varepsilon_t^v u_*^v.$$

For births/deaths, (L_t^v) is additionally clipped below at zero.

Without same-year target statistics,

$$L_t^v = \ell_*^v, \quad U_t^v = u_*^v.$$

4.5 Compress and normalize raw predictions

Compute prediction quartiles, standard deviation, and

$$I_t^v = Q_{0.75}(z_t^v) - Q_{0.25}(z_t^v),$$

$$a_t^v = \begin{cases} I_t^v, & I_t^v > 10^{-5}, \\ \sigma_t^v, & I_t^v \leq 10^{-5}, \sigma_t^v > 10^{-5}, \\ 0.01, & \text{otherwise.} \end{cases}$$

These statistics use finite predictions on land with positive population.

Define fences

$$T^- = Q_{0.25} - 1.5a, \quad T^+ = Q_{0.75} + 1.5a,$$

and compression

$$R(z) = \begin{cases} T^+ + a \log \left(1 + \frac{z - T^+}{a} \right), & z > T^+, \\ T^- - a \log \left(1 + \frac{T^- - z}{a} \right), & z < T^-, \\ z, & \text{otherwise.} \end{cases}$$

Let

$$R_{\min} = \min_i R(z_i), \quad R_{\max} = \max_i R(z_i).$$

The normalized prediction is

$$u_{i,t}^v = \begin{cases} \text{clip} \left(\frac{R(z_{i,t}^v) - R_{\min}}{R_{\max} - R_{\min}}, 0, 1 \right), & R_{\max} > R_{\min}, \\ 1/2, & R_{\max} = R_{\min}. \end{cases}$$

Finally, the calibrated factor or rate is

$$f_{i,t}^v = L_t^v + u_{i,t}^v (U_t^v - L_t^v).$$

Invalid or excluded cells in the normalized raster remain initialized to zero, rather than being explicitly stored as missing.

5. Preliminary births and deaths

Define the actual-data lock

$$o_{i,t}^v = \mathbf{1}_{\{\text{source raster exists and } A_{i,t}^v > 0\}}.$$

Valid source zeros are therefore **not** locked.

The preliminary births are

$$B_{i,t}^0 = \begin{cases} A_{i,t}^B, & o_{i,t}^B = 1, \\ \min \left(f_{i,t}^B Q_{i,t}^B, 1.5 Q_{i,t}^B \right), & o_{i,t}^B = 0. \end{cases}$$

Preliminary sex-specific deaths are

$$\tilde{D}_{i,t}^s = \begin{cases} A_{i,t}^{D_s}, & o_{i,t}^{D_s} = 1, \\ \min \left(f_{i,t}^{D_s} Q_{i,t}^{D_s}, P_{i,t} \right), & o_{i,t}^{D_s} = 0. \end{cases}$$

When neither sex is anchored, define

$$\pi_{m,i,t}^D = \begin{cases} \frac{u_{i,t}^{D_m}}{u_{i,t}^{D_m} + u_{i,t}^{D_f}}, & u_{i,t}^{D_m} + u_{i,t}^{D_f} > 0, \\ 1/2, & \text{otherwise.} \end{cases}$$

Then

$$D_{m,i,t}^0 = \pi_{m,i,t}^D (\tilde{D}_{i,t}^m + \tilde{D}_{i,t}^f),$$

$$D_{f,i,t}^0 = (1 - \pi_{m,i,t}^D) (\tilde{D}_{i,t}^m + \tilde{D}_{i,t}^f).$$

If either sex is anchored, this redistribution is skipped:

$$D_{s,i,t}^0 = \tilde{D}_{i,t}^s.$$

Let

$$D_{i,t}^0 = D_{f,i,t}^0 + D_{m,i,t}^0.$$

6. Preliminary migration and its sex split

6.1 Model prediction and residual anchoring

The modeled migration is

$$M_{i,t}^{\text{pred}} = P_{i,t} f_{i,t}^M.$$

Let $(o_{i,t}^M)$ indicate that the UNWPP birth, female-death, male-death, and population-delta files exist and the resulting residual is numeric.

Then

$$\tilde{M}_{i,t} = \begin{cases} A_{i,t}^M, & o_{i,t}^M = 1, \\ M_{i,t}^{\text{pred}}, & o_{i,t}^M = 0. \end{cases}$$

Because missing input values are replaced with zero, file availability can effectively anchor cells that lack genuine source coverage.

6.2 Initial global balancing

For positive-population cells, define

$$\kappa_t = \begin{cases} -\frac{\sum_i \tilde{M}_{i,t}}{\sum_i (1 - o_{i,t}^M) P_{i,t}}, & \sum_i (1 - o_{i,t}^M) P_{i,t} > 0, \\ 0, & \text{otherwise.} \end{cases}$$

Then

$$M_{i,t}^0 = \widetilde{M}_{i,t} + (1 - o_{i,t}^M)P_{i,t}\kappa_t.$$

This produces zero aggregate migration only if there is adjustable population and the summation domain matches the output domain.

6.3 Rogers–Castro-style sex potentials

The prescribed schedule is

$$W_s(x) = 0.02e^{-0.1x} + 0.06 \exp \left[-0.1(x - \mu_s) - e^{-0.3(x - \mu_s)} \right] + 0.003,$$

with

$$\mu_f = 20, \quad \mu_m = 22.5.$$

For this schedule, evaluation ages are

$$x_a^{RC} = \begin{cases} 0.5, & a = 0, \\ 3, & a = 1, \\ \text{lower age label} + 2.5, & a \geq 2. \end{cases}$$

Notice that the ages 1–4 schedule uses 3, whereas the mortality proxy uses midpoint 2.

Define sex potentials

$$V_{i,t}^s = \sum_a N_{i,t,a}^s W_s(x_a^{RC}).$$

Then

$$\pi_{f,i,t}^M = \begin{cases} \frac{V_{i,t}^f}{V_{i,t}^f + V_{i,t}^m}, & V_{i,t}^f + V_{i,t}^m > 0, \\ 0.488, & \text{otherwise,} \end{cases}$$

$$\pi_{m,i,t}^M = 1 - \pi_{f,i,t}^M,$$

and

$$M_{i,t}^{s,0} = \pi_{s,i,t}^M M_{i,t}^0.$$

The schedule allocates a signed net total; it does not estimate separate sex-specific immigration and emigration.

7. Final demographic reconciliation

This stage executes only when all three migration rasters, the delta raster, and the working birth/death arrays are available.

Work below on the active cells having positive population and valid migration/delta values.

7.1 Birth bounds

Let

$$B_i^- = \begin{cases} B_i^0, & o_i^B = 1, \\ 0, & o_i^B = 0, \end{cases}$$

and

$$B_i^+ = \begin{cases} B_i^0, & o_i^B = 1, \\ 1.5Q_i^B, & o_i^B = 0, Q_i^B > 0, \\ \max(B_i^0, 0.06P_i), & o_i^B = 0, Q_i^B \leq 0. \end{cases}$$

7.2 Total-death bounds

Let $(o_f = o^{D_f})$ and $(o_m = o^{D_m})$.

$$(D_i^-, D_i^+) = \begin{cases} (D_i^0, D_i^0), & o_f = o_m = 1, \\ (D_{f,i}^0, \max(D_{f,i}^0, P_i)), & o_f = 1, o_m = 0, \\ (D_{m,i}^0, \max(D_{m,i}^0, P_i)), & o_f = 0, o_m = 1, \\ (0, P_i), & o_f = o_m = 0. \end{cases}$$

7.3 Implied migration bounds

From

$$g_i = B_i - D_i + M_i,$$

the feasible migration interval is

$$M_i^- = g_i - B_i^+ + D_i^-,$$

$$M_i^+ = g_i - B_i^- + D_i^+.$$

Global zero-sum feasibility requires

$$\sum_i M_i^- \leq 0 \leq \sum_i M_i^+.$$

If infeasible, the code warns but continues; it cannot satisfy all constraints.

7.4 Solve the population-weighted migration shift

Define

$$M_i(\lambda) = \text{clip} (M_i^0 + P_i \lambda, M_i^-, M_i^+).$$

Choose a root of

$$\sum_i M_i(\lambda) = 0.$$

Then

$$M_i^* = M_i(\lambda^*).$$

The code uses an initial bracket $([-10, 10])$, limited bracket expansion, and up to 45 bisection iterations. Its absolute aggregate stopping tolerance is (10^{-5}) .

This is equivalent, when feasible and solved exactly, to

$$\underset{M}{\text{minimize}} \quad \frac{1}{2} \sum_i \frac{(M_i - M_i^0)^2}{P_i}$$

subject to

$$M_i^- \leq M_i \leq M_i^+, \quad \sum_i M_i = 0.$$

The optimal migration vector is unique for positive (P_i) ; the shift parameter need not be unique on a flat segment.

7.5 Project births and deaths onto local accounting

The required natural increase is

$$n_i^* = g_i - M_i^*.$$

The permissible birth interval is

$$L_i^B = \max(B_i^-, n_i^* + D_i^-),$$

$$U_i^B = \min(B_i^+, n_i^* + D_i^+).$$

The unconstrained equal-weight projection is

$$B_i^{\text{unc}} = \frac{B_i^0 + D_i^0 + n_i^*}{2}.$$

Therefore,

$$B_i^* = \text{clip} (B_i^{\text{unc}}, L_i^B, U_i^B),$$

$$D_i^* = B_i^* - n_i^*.$$

This minimizes

$$(B_i - B_i^0)^2 + (D_i - D_i^0)^2$$

subject to the local balance and bounds.

Observed births are explicitly reset to their locked value.

When all three vital counts are observed, the code directly uses

$$B_i^* = B_i^0, \quad D_{s,i}^* = D_{s,i}^0, \quad M_i^* = g_i - B_i^0 + D_i^0.$$

7.6 Reallocate reconciled deaths between sexes

If both death counts are observed, preserve both.

If only female deaths are observed,

$$D_{f,i}^* = D_{f,i}^0, \quad D_{m,i}^* = \max(0, D_i^* - D_{f,i}^0).$$

If only male deaths are observed,

$$D_{m,i}^* = D_{m,i}^0, \quad D_{f,i}^* = \max(0, D_i^* - D_{m,i}^0).$$

If neither is observed, let

$$\eta_{m,i} = \begin{cases} D_{m,i}^0/D_i^0, & D_i^0 > 0, \\ 0.512, & D_i^0 = 0. \end{cases}$$

Then

$$D_{m,i}^* = \eta_{m,i} D_i^*, \quad D_{f,i}^* = (1 - \eta_{m,i}) D_i^*.$$

7.7 Update sex-specific migration

The code allocates the migration change

$$\delta M_i = M_i^* - M_i^0$$

using the existing migration-sex proportions:

$$\eta_{s,i}^M = \begin{cases} \frac{M_i^{s,0}}{M_i^{f,0} + M_i^{m,0}}, & M_i^{f,0} + M_i^{m,0} \neq 0, \\ 0.488, & s = f, \text{ sum} = 0, \\ 0.512, & s = m, \text{ sum} = 0. \end{cases}$$

Thus

$$M_i^{s,*} = M_i^{s,0} + \eta_{s,i}^M \delta M_i.$$

For initially nonzero, internally consistent migration this reduces to

$$M_i^{s,*} = \pi_{s,i}^M M_i^*.$$

If initial migration was exactly zero, newly introduced migration uses the fallback sex split rather than recovering the Rogers–Castro potentials.

The implementation skips migration updates smaller than (10^{-7}) , so its stored outputs need not close exactly even before Float32 rounding.

8. Compact form of the complete system

Let:

- $(\mathcal{C}_{v,t})$: the target-bound, tail-compression, and min–max calibration operator from Section 4;
- $(\mathcal{A}_v)$: positive-source-value override;
- $(\mathcal{H})$: default country-bin Whittaker graduation;
- $(\mathcal{S})$: final age–sex source compositing;
- $(\mathcal{I}_w)$: weighted decreasing isotonic projection.

Then the system is:

Age–sex structure

$$p_{i,t,a}^s = \sum_{\tau} \alpha_{\tau}(t) \frac{e^{\tilde{X}_{i,t}^{\top} \beta_{\tau,a}^s}}{\sum_{r,b} e^{\tilde{X}_{i,t}^{\top} \beta_{\tau,b}^r}},$$

with the premodern-model substitution before 1500,

$$\begin{aligned} R_{b,t,a}^s &= \sum_{i \in \mathcal{E}_{b,t}} P_{i,t}^A p_{i,t,a}^s, & G &= \mathcal{H}(R), \\ N_{i,t,a}^{s,\text{model}} &= P_{i,t}^A \frac{p_{i,t,a}^s (G_{b,t,a}^s / R_{b,t,a}^s)}{\sum_{r,c} p_{i,t,c}^r (G_{b,t,c}^r / R_{b,t,c}^r)}, \\ N &= \mathcal{S}(N^{\text{model}}, H, U, W), \end{aligned}$$

with the zero-support and HMD-bypass rules specified above.

Vital-event proxies

$$\begin{aligned} Q_{i,t}^B &= N_{i,t,0}^f + N_{i,t,0}^m, \\ r_{i,t} &= \frac{\log(P_{i,t}/P_{i,t-})}{h_t}, & \hat{S}_{i,t}^s &= \mathcal{I}_w \left(\frac{N_{i,t,a}^s}{w_a} e^{r_{i,t} x_a} \right), \end{aligned}$$

$$Q_{i,t}^{D_s} = \sum_a N_{i,t,a}^s \hat{\mu}_{i,t,a}^s.$$

Preliminary event estimates

$$f_{i,t}^v = \mathcal{C}_{v,t} \left(Z_{i,t}^\top \theta^v(t) \right),$$

$$B^0 = \mathcal{A}_B(\min(f^B Q^B, 1.5Q^B)),$$

$$\tilde{D}^s = \mathcal{A}_{D_s}(\min(f^{D_s} Q^{D_s}, P)),$$

$$(D_f^0, D_m^0) = \text{normalized-score sex redistribution of } (\tilde{D}^f, \tilde{D}^m),$$

subject to source locks.

Preliminary migration

$$g = \frac{\Delta P}{h}, \quad A^M = g - A^{B,U} + A^{D_f,U} + A^{D_m,U},$$

$$\widetilde{M} = o^M A^M + (1 - o^M) P f^M,$$

$$M^0 = \widetilde{M} + (1 - o^M) P \kappa, \quad \sum_i M_i^0 = 0 \quad \text{when adjustable support exists,}$$

$$M^{s,0} = \pi_s^M M^0, \quad \pi_s^M \propto \sum_a N_a^s W_s(x_a^{RC}).$$

Final reconciliation

$$M^- = g - B^+ + D^-, \quad M^+ = g - B^- + D^+,$$

$$M_i^* = \text{clip}(M_i^0 + P_i \lambda^*, M_i^-, M_i^+), \quad \sum_i M_i^* = 0,$$

$$n_i^* = g_i - M_i^*,$$

$$B_i^* = \text{clip} \left(\frac{B_i^0 + D_i^0 + n_i^*}{2}, \max(B_i^-, n_i^* + D_i^-), \min(B_i^+, n_i^* + D_i^+) \right),$$

$$D_i^* = B_i^* - n_i^*,$$

$$(D_{f,i}^*, D_{m,i}^*) = \text{source-locked allocation of } D_i^*,$$

$$M_i^{s,*} = M_i^{s,0} + \eta_{s,i}^M (M_i^* - M_i^0).$$

Therefore, on the feasible reconciled domain and in exact arithmetic,

$$\boxed{\frac{\Delta P_{i,t}}{h_t} = B_{i,t}^* - D_{i,t}^{f,*} - D_{i,t}^{m,*} + M_{i,t}^{f,*} + M_{i,t}^{m,*}}$$

and

$$\sum_i \left(M_{i,t}^{f,*} + M_{i,t}^{m,*} \right) = 0.$$

The final accounting constrains total population change, but it does not require successive age–sex pyramids to evolve consistently under the estimated births, deaths, and migration. Those are essentially calculated from predicted age-sex pyramids as residuals.

Counterintuitively, this means that age-sex pyramids resolve migration first since the system is global in scope, and therefore closed. Net migration therefore sums to 0 at a global level, making it easiest to resolve.

Section 2. Whittaker-Henderson Report

Report - Current Whittaker-Henderson (Huber loss) tests in replacement of PAVA.

Tested for 1600AD, 1940AD for select countries. This is a partial test of the system in practice using priors.

This document analyses the empirical population pyramids generated by the new **ISO3-binned Whittaker-Henderson graduation with Huber loss and soft monotonicity penalisation**, sampled directly over real ISO3 country areal masks derived from [geocodes.png](#) and [geocodes.csv](#).

1. Architectural Summary: ISO3 Country Bins

Rather than executing non-linear numerical coordinate bisection per individual pixel across > 800.000 inhabited grid cells (which was computationally prohibitive and caused 10-minute runtimes), the architecture employs **ISO3 country binning**:

1. **Pass 1 (Aggregation)**: Raster pixels are pre-indexed against their ISO3 territorial code via a RGB hash table. Each pixel's multinomial logit (MNL) cohort density weighted by local Stadester population is accumulated into its corresponding country bin (≤ 189 bins worldwide).
2. **Pass 2 (Whittaker-Henderson Graduation)**: Whittaker-Henderson graduation with Huber loss ($\delta = 0,05$), third-order difference smoothing ($\lambda = 20,0$), and soft monotonicity penalty ($\mu = 1500,0$) is executed once per active country bin. Across all 189 countries, this step finishes in 0,46 **seconds**.
3. **Pass 3 (Dasymetric Projection)**: The graduated cohort scaling factors for each country are dasymetrically applied to each pixel's local MNL probabilities, maintaining sub-national spatial variation whilst strictly closing total population to the local Stadester cell population.

Total runtime across all 36 cohorts for both 1600 and 1940, including 72 full-resolution disk raster writes and areal mask sampling, was reduced to **2 minutes 10 seconds**.

2. Year 1600 Results

France (FRA) — Total Population: 17,492 M

Cohort	Age Band	Male Pop	Female Pop	Total Pop	Sex Ratio (<i>M/F</i>)	% Total	Monotonic?

Cohort	Age Band	Male Pop	Female Pop	Total Pop	Sex Ratio (M/F)	% Total	Monotonic?
80	80+	1.259.053	1.939.701	3.198.754	0,65	3,52%	✓

Observation: The raw input MNL model for Japan 1940 contained an extreme structural artefact in elderly cohorts: raw female cohort 65 spiked to 3,74 M and cohort 75 spiked to 4,26 M (totaling 4,78 M and 4,62 M), before crashing to 0,70 M at age 80+.

Whittaker-Henderson smoothly attenuated these spikes (reducing age 65 from 4,78 M to 3,79 M and lifting age 80 from 0,70 M to 3,20 M). Because μ is a soft penalty ($\mu = 1500$), it gracefully accommodates this massive +1,8 M empirical spike without brutal step-clipping. If strict zero-tolerance monotonicity is desired in these extreme edge cases, increasing μ to 5000 will force a complete monotonically decreasing slope.
